January 23, 2023, Conference "Homological Mirror Symmetry", Miami

# Introduction

Let  $X$ ,  $\dim_{\mathbb{C}} X = n$  be a Kähler manifold endowed with a holomorphic Morse function  $f$  (“superpotential”). Denote its critical set by  $\text{Crit}(f) = \{x_1, \dots, x_k\}$ , and the corresponding set of critical values by  $S := \text{Critval}(f) = \{z_1, \dots, z_k\}$ ,  $f(x_i) = z_i$ . Let us assume that all  $z_i$ ’s are distinct. Critical points  $x_i$  generate the Morse complex of  $(X, f)$ . Generically there is no interaction between critical points, since  $\text{ind}(x_i) = n$ ,  $1 \leq i \leq k$ . Morse differential becomes non-trivial for the function  $f/\hbar$  and “Stokes rays”  $\text{Arg}(\hbar) = \text{Arg}(z_i - z_j) \subset \mathbb{C}_{\hbar}^*$ . Similar story for the Floer complex of the pair of holomorphic Lagrangian submanifolds  $L_0 = X$ ,  $L_1 = \text{graph}(df)$  in a complex symplectic manifold  $(T^*X, \omega^{2,0})$  (generically: no pseudo-holomorphic discs).

# Wall-crossing structures in holomorphic Morse theory

In order to take into account non-triviality of the Morse differential for some directions we suggest to consider for the pair  $(X, f)$  (equivalently  $(L_0, L_1)$ ) the corresponding **wall-crossing structure** introduced by Maxim Kontsevich and myself in 2013. I will explain later the specific WCS for the pair  $(X, f)$ . For the general definition and discussion of WCS I refer to [arXiv:1303.3253](#) or to [arXiv:2005.10651](#). In the latter paper we also introduced an important subclass of **analytic wall-crossing structures**. Role of analytic WCS in the theory: they give rise to resurgent series.

# Idea of the approach from the perspective of Holomorphic Floer Theory

Main aim of my talk is to explain a **conjectural approach** to the resurgence of perturbative series in the **complexified Chern-Simons theory**. It is based on analytic WCS defined in terms of certain **pairs of complex Lagrangian subvarieties**. In this way the subject of my talk can be thought of as a particular application of our program **“Holomorphic Floer Theory”**. We discussed many other aspects of HFT at previous HMS workshops.

**Rough idea of the approach:** critical points of the CS functional (i.e. flat connections) correspond to intersection points of the complex Lagrangian subvarieties. Borel transforms of the local perturbative expansions at critical points can be combined in a unique **multivalued analytic function** provided we know how the critical points “interact”. In the case of rigid flat connections the interaction is encoded in the “Stokes indices”, which is the properly defined number of gradient lines of  $Re(CS)$  between pairs of critical points. This idea is reminiscent to the one in the “algebra of the infrared” story (Gaiotto-Moore-Witten, and a mathematical treatment of their work in the papers written jointly with Kapranov, Kontsevich, Soukhanov). The underlying “CS WCS” can be described in different ways. One way (will not be discussed today) uses our theory of quantum wave functions. Quantum wave functions are cyclic vectors of holonomic  $DQ$ -modules associated to the complex Lagrangian subvarieties. In a sense this is the “*B-side of HFT*”. Another one (which will be discussed today) is based on a conjectural Hodge structure of countable rank. In a sense this is the “*A-side of HFT*”. In general the relation between  $A$  and  $B$  sides of HFT is *not* a HMS but rather a Riemann-Hilbert correspondence.

# Global and local Fukaya-Seidel categories

Wall-crossing structures I am going to talk about today underly the so-called  $2d$  wall-crossing formulas (a.k.a. as Cecotti-Vafa or Picard-Lefschetz WCF). These formulas are corollaries of the *isomorphism of local and global Betti cohomology*. I start by recalling the story in the framework of Landau-Ginzburg model.

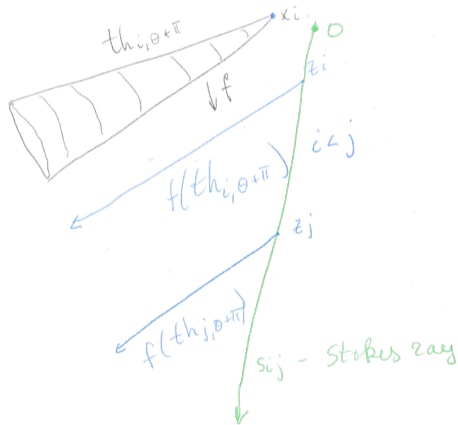

Assume for simplicity that  $f$  is Morse (this condition can and will be relaxed). Recall that under some mild conditions one can describe the **global** Fukaya-Seidel category  $FS(X, f)$  in terms of the **local** Fukaya-Seidel categories  $FS(U_\varepsilon(z_i), f)$ ,  $1 \leq i \leq k$ , where  $U_\varepsilon(z_i)$  is a small tubular neighborhood of the critical locus  $f^{-1}(z_i)$  of the critical value  $z_i$ .

# Thimbles

In the Morse case global (resp. local) FS-categories are generated by global (resp. local) thimbles.

For a given  $\theta = \text{Arg}(\hbar) \in \mathbb{R}/2\pi\mathbb{Z} = S^1_\theta$  a **thimble**  $th_{z_i, \theta + \pi}$  is defined as the union of gradient lines (for the Kähler metric) of the function  $\text{Re}(e^{-i\theta} f)$  which originate at the critical point  $x_i \in X$ . Then  $f(th_{z_i, \theta + \pi})$  is a ray  $\text{Arg}(z) = \theta + \pi$  emanating from the critical value  $z_i \in S$ .

# Global thimbles as generators of the global FS category

# Local thimbles as generators of the local FS categories

○

# Betti local-to-global isomorphism

Homology classes of thimbles  $th_{z_i, \theta + \pi}$ ,  $1 \leq i \leq k$  generate the lattice of relative homology  $\Gamma_\theta = H_n(X, f^{-1}(z), \mathbb{Z}) / \text{tors} \simeq \mathbb{Z}^k$ . Here  $|z| \gg 1$ ,  $\text{Arg}(z) = \theta + \pi$ . Variation of  $\theta$  gives a local system of lattices on  $S_\theta^1$  with the fiber  $\Gamma_\theta = H_n(X, f^{-1}(\infty), \mathbb{Z}) / \text{tors}$ . We can replace  $\theta \in \mathbb{R}/2\pi\mathbb{Z}$  by  $\hbar \in \mathbb{C}^*$ ,  $\text{Arg}(\hbar) = \theta + \pi$  and get a local system of lattices on  $\mathbb{C}_\hbar^*$ .

This local system of **global** relative homology groups  $H_n^{\text{Betti}, \theta + \pi}(X, f)$  can be identified with the direct sum over all  $z_i$  of similarly defined **local** relative homology groups generated by local thimbles. We will often use the cohomology groups instead. The direct sum

$H_{\text{Betti}, \text{loc}, \theta + \pi}^\bullet(X, f)$  of the local cohomology groups over all  $z_i$  is called **Betti local cohomology** of  $(X, f)$  in the direction  $\theta + \pi$ . Then at the level of cohomology the equivalence of global and local FS-categories amounts to the **Betti local-to-global isomorphism**. Taking two rays with slopes  $\theta_\pm = \text{Arg}(z_i - z_j) \pm \varepsilon$  one obtains the Stokes isomorphism between Betti local cohomology at  $z_i$  and  $z_j$ . Collection of relative local cohomology groups together with the Stokes isomorphisms for all pairs  $z_i, z_j$  is the same as a perverse sheaf  $\mathcal{F}$  on  $\mathbb{C}$  such that  $\mathbf{R}\Gamma(\mathbb{C}, \mathcal{F}) = 0$ .

# Betti local cohomology in terms of the sheaf of vanishing cycles

Assume  $X$  is *affine algebraic*, *Kähler*,  $\dim_{\mathbb{C}} X = n$ ,  $f : X \rightarrow \mathbb{C}$  is *regular Morse* function. Then the local Betti cohomology can be defined via the cohomology with coefficients in the sheaf of vanishing cycles:

$$H_{Betti,loc,\hbar}^{\bullet}(X, f) = \bigoplus_{z \in \{z_1, \dots, z_k\}} H^{\bullet}((f/\hbar)^{-1}(z/\hbar), \varphi_{\frac{f-z}{\hbar}}(\underline{\mathbb{Z}}_X)).$$

This formula holds without the assumption that  $f$  is Morse.

# Exponential integrals

I am going to use the same geometry but in a different framework. Morally it corresponds to the Fourier transform of the perverse sheaf  $\mathcal{F}$ . Then Betti local-to-global isomorphism gives rise to the wall-crossing formulas and wall-crossing structure for **exponential integrals**. I review the finite-dimensional story in the Morse case and then will discuss its generalization to the non-Morse and the infinite-dimensional cases.

Let us fix the top-degree holomorphic form  $vol$  on  $X$  and consider the following collection of exponential integrals for those  $\hbar \in \mathbb{C}^*$  which do not belong to the **Stokes rays**  $s_{ij} := \{\hbar \mid \text{Arg}(\hbar) = \text{Arg}(z_i - z_j), i \neq j\}$ :

$$I_i(\hbar) = \int_{th_{z_i, \theta + \pi}} e^{f/\hbar} vol.$$

Assume that the set of critical values  $S = \{z_1, \dots, z_k\}$  is in generic position in the sense that no straight line contains three points from  $S$ . Then a Stokes ray contains two different critical values, say  $z_i, z_j$  which can be ordered  $z_i < z_j$  by their proximity to the vertex.

# Wall-crossing formulas

Picard-Lefschetz formulas imply the following fact.

## Lemma

*If in the  $\hbar$ -plane we cross the Stokes ray  $s_{ij} = s_{\theta_{ij}}$  containing critical values  $z_i, z_j, z_i < z_j, \theta_{ij} = \text{Arg}(z_i - z_j)$ , then the integral  $I_i(\hbar)$  changes such as follows:*

$$I_i(\hbar) \mapsto I_i(\hbar) + n_{ij} I_j(\hbar),$$

*where  $n_{ij} \in \mathbb{Z}$  is the number of gradient trajectories of the function  $\text{Re}(e^{i(\text{Arg}(z_i - z_j))} f)$  joining critical points  $x_i$  and  $x_j$ .*

Let us modify the exponential integrals. This will be useful in the infinite-dimensional case as well.

$$I_i^{mod}(\hbar) := \left( \frac{1}{2\pi\hbar} \right)^{n/2} e^{-z_i/\hbar} I_i(\hbar).$$

Then as  $\hbar \rightarrow 0$  the stationary phase expansion gives a formal series

$$I_i^{mod}(\hbar) = c_{i,0} + c_{i,1}\hbar + \dots \in \mathbb{C}[[\hbar]],$$

where  $c_{i,0} \neq 0$ . The jump of the modified exponential integral when we cross the Stokes ray  $s_j$  is given by  $\Delta(I_i^{mod}(\hbar)) = n_{ij} I_j^{mod}(\hbar) e^{-(z_i - z_j)/\hbar}$ .

# RH problem

Wall-crossing formulas give rise to a Riemann-Hilbert problem which in turn gives rise to a **holomorphic vector bundle** obtained by gluing along Stokes rays trivial bundles in sectors bounded by Stokes rays. Explicitly, the vector  $\bar{I}^{mod}(\hbar) = (I_1^{mod}(\hbar), \dots, I_k^{mod}(\hbar))$ ,  $k = |S|$  satisfies the Riemann-Hilbert problem on  $\mathbb{C}$  with known jumps across the Stokes rays and known asymptotic expansion as  $\hbar \rightarrow 0$ . In this way we obtain the data consisting of a holomorphic vector bundle on  $\mathbb{C}_{\hbar}$  and its section. These data encode analytic and resurgence properties of any exponential integral of the type  $I_C(\hbar) = \int_C e^{f/\hbar} vol$  as  $\hbar \rightarrow 0$ .

Same data can be derived from the pair  $(X, \text{graph}(df))$  of Lagrangian submanifolds of  $(T^*X, \omega = \text{Re}(\omega^{2,0}/\hbar))$ . Then  $n_{ij}$  appears as the number of pseudo-holomorphic discs with boundary on  $X \cup \text{graph}(df)$  for  $\hbar \in \mathbb{R}_{>0} \cdot (z_i - z_j)$ .

Exponential integral can be treated as exponential period representing the pairing of the (twisted) global de Rham and global Betti cohomology. From the point of view of HFT this pairing is an incarnation of an equivalence of (some) Fukaya category of  $T^*X$  and the (some) category of holonomic  $DQ$ -modules on  $T^*X$ . This equivalence is an example of our **generalized RH-correspondence**.

# Wall-crossing structure for exponential integrals

In general WCS is a local system of **stability data on a graded Lie algebra**. In our case it is a local system on  $\mathbb{C}_\hbar^*$  (or the circle of directions  $S_\theta^1$ ). Explicitly it is given by the following:

i) local system of lattices  $\Gamma_\hbar = \Gamma_{\text{Arg}(\hbar)} \simeq \mathbb{Z}^k$ ,

ii) local system of central charges  $Z_\hbar(e_i) = z_i/\hbar$ ,  $1 \leq i \leq k$  for the standard basis  $e_i$ ,  $1 \leq i \leq k$  of  $\mathbb{Z}^k$ .

iii) Local system  $\Gamma$ -graded Lie algebras  $\mathfrak{g}_\hbar = H_{\text{Betti,loc},\hbar}^\bullet(X, f) \otimes \mathbb{C}$ .

The RHS can be written as

$$\bigoplus_{i,j} \text{Hom}(H^\bullet((f/\hbar)^{-1}(D_\varepsilon(z_i/\hbar)), (f/\hbar)^{-1}(\frac{z_i}{\hbar} - \varepsilon), \mathbb{C}), H^\bullet((f/\hbar)^{-1}(D_\varepsilon(z_j/\hbar)), (f/\hbar)^{-1}(\frac{z_j}{\hbar} - \varepsilon), \mathbb{C}))$$

where  $D_\varepsilon(p)$  is a small disc centered at  $p$ . In algebra-geometric framework it is better to use  $H^\bullet(\text{Crit}(f), \varphi_{f/\hbar}(\mathbb{Z}))$ , where  $\varphi_{f/\hbar}$  is the functor of the sheaf of vanishing cycles of  $f/\hbar$ .

iv) Final piece of WCS consists of Stokes automorphisms which arise from the Betti local-to-global isomorphisms. In the Morse case Stokes isomorphisms are derived from the collection of Stokes indices  $n_{ij}$ .

# Local relative cohomology

# Pairs of complex Lagrangian subvarieties related to Chern-Simons theory

1) Let  $M^3$  be a compact oriented 3-manifold. Let  $G_c$  be a compact group and  $G$  be its complexification. Representing  $M^3$  via a surgery along a knot  $K \subset M^3$  one gets a complex symplectic manifold (more precisely, symplectic stack) of flat  $G$ -connections on the boundary of a small neighborhood of  $K$ . One has two complex Lagrangian subvarieties  $L_{in}$  and  $L_{out}$  consisting of those connections which can be extended inside (resp. outside) of a small neighborhood of  $K$ . The intersection  $L_{in} \cap L_{out}$  can be identified with the set of flat  $G$ -connections on  $M^3$ . It is the same as the set of critical points of the (complexified) multivalued Chern-Simons functional

$$CS(A) = \int_{M^3} \text{Tr} \left( \frac{1}{2} A \wedge dA + \frac{1}{3} A \wedge A \wedge A \right).$$

To avoid stacks one can work with the infinite-dimensional *manifold*  $\mathcal{A}_C^{fr}$  of  $G$ -connections trivialized at  $x_0 \in M^3$ . Then  $CS$  becomes a *multivalued* holomorphic function on  $\mathcal{A}_C^{fr}$ . We can either consider it as a function on the universal abelian covering  $\widehat{\mathcal{A}}_C^{fr}$  or work with the holomorphic closed 1-form  $\alpha_{CS} = dCS$ .

## $K_2$ -Lagrangian subvarieties

The pair below gives in the end another approach to the same WCS. I am not going to discuss it today.

2) Another example related to the Chern-Simons theory and to the quantum dilogarithm

$$L_0 := \{(q_1, p_1, q_2, p_2, \dots, q_n, p_n) \in \mathbb{C}^{2n} \mid e^{q_i} + e^{p_i} = 1, i = 1, \dots, n\} \subset (\mathbb{C}^*)^{2n}$$

which is a complex Lagrangian submanifold of the manifold  $(\mathbb{C}^*)_{x_1, \dots, x_n, y_1, \dots, y_n}^{2n}$  endowed with the standard symplectic form  $\omega^{2,0} = \sum_{1 \leq i \leq n} \frac{dx_i}{x_i} \wedge \frac{dy_i}{y_i}$ . Here  $x_i = e^{q_i}$ ,  $y_i = e^{p_i}$ ,  $1 \leq i \leq n$ . Fix an integer symmetric matrix  $(a_{ij})_{1 \leq i, j \leq n}$  and consider the abelian subgroup in  $\mathbb{Z}^n$ .

$$P = \{(q_1, p_1, \dots, q_n, p_n) \mid p_j = \sum_{1 \leq i \leq n} a_{ij} q_i\}, 1 \leq j \leq n.$$

Finally  $L_1 := L_P \subset (\mathbb{C}^*)^{2n}$  is the corresponding Lagrangian torus.

When quantizing the CS theory one should give a meaning to the Feynman integral over the totally real subvariety  $\mathcal{A}_c^{fr} \subset \mathcal{A}_{\mathbb{C}}^{fr}$  of  $G_c$ -connections on principal  $G_c$ -bundles trivialized (framed) at the point  $x_0$

$$I(k) = \int_{\mathcal{A}_c^{fr}} e^{kCS(A)/2\pi i} \mathcal{D}A.$$

Here  $k \in \mathbb{Z}_{>0}$  is the level of the CS theory. If understood properly, this partition function should be given a mathematical meaning in terms of a 3d TQFT, defined in terms of representation theory (the work of Reshetikhin, Turaev, Viro, Witten and others).

I would like to approach this ill-defined exponential integral perturbatively as a function  $I = I(\hbar)$  of  $\hbar = 2\pi i/k$ ,  $\hbar \rightarrow 0$  by analogy with finite-dimensional exponential integrals. Then the level  $k$  does not have to be integer. There is a conjecture which relates  $I(k)$  with integer  $k$  to this approach.

I am going to explain our approach assuming positive answers to several foundational questions. E.g. I will assume that the *CS functional* considered as a holomorphic function  $\widehat{\mathcal{A}}_{\mathbb{C}}^{fr} \rightarrow \mathbb{C}$  gives rise to a locally trivial infinite-dimensional fiber bundle outside of the set of critical values.

Under some choices (which include the so-called *orientation data*) one can define the sheaf of vanishing cycles  $\varphi_{CS}(\mathbb{Z})$ . Maybe this is already a theorem. Sometimes I will abuse the notation and treat *CS* as an antiderivative of the 1-form  $\alpha_{CS}$  in a small neighborhood of the zero locus  $\mathcal{Z}(\alpha_{CS})$  with fixed value on each connected component. Then the sheaf of vanishing cycles is supported on the zero locus.

Let  $\mathcal{Z}(\alpha_{CS}) = \sqcup_{j \in J} \mathcal{Z}_j(\alpha_{CS})$  be the decomposition of the zero locus into the finite union of connected components, i.e.  $J = \pi_0(\mathcal{Z}(\alpha_{CS}))$ .

Physics predicts existence of a  $\mathbb{Z}$ -equivariant linear map

$$R_j : H_c^0(\mathcal{Z}_j(\alpha_{CS}), \varphi_{CS}(\mathbb{Z})) \rightarrow \overline{\mathbb{C}((\hbar))}[\log \hbar],$$

which should be thought of as the formal expansion in  $\hbar \rightarrow 0$  of the ill-defined “local Feynman integral”  $\int_{\gamma_j} e^{\frac{CS}{\hbar}} \text{vol}$ ,  $\hbar = 2\pi i/k$ . Here  $\gamma_j$  should be thought of (via Poincaré duality) as a “middle-dimensional integration cycle”, which coincides with the local thimble in the case when  $\mathcal{Z}_j(\alpha_{CS})$  is an isolated simple zero. Informally  $\text{vol}$  is a “complexification of the Feynman measure” restricted to  $\gamma_j$ . The algebraic closure  $\overline{\mathbb{C}((\hbar))} = \cup_{N \geq 1} \mathbb{C}((\hbar^{1/N}))$ .

$\mathbb{Z}$ -action on the LHS comes from the standard monodromy action on the sheaf of vanishing cycles, while the  $\mathbb{Z}$ -action on the RHS is given by

$\hbar^{1/N} \mapsto e^{2\pi i/N} \hbar^{1/N}$ ,  $\log \hbar \mapsto \log \hbar + 2\pi i$ ,  $N \geq 1$ . The degree of the compactly supported cohomology group (it is dual to the space of integration cycles) is chosen in such a way that it is compatible with the middle perversity. Hence the middle-dimensional integration cycle corresponds to degree zero.

We will consider  $R_j$  as a black box, without trying to give it a mathematical meaning. We have another approach to CS theory via quantum wave functions. In that approach  $R_j$  can be defined rigorously, but then one has to show that the rigorous definition agrees with physics. In a special case when  $\mathcal{Z}_j(\alpha_{CS})$  is a  $G$ -orbit of a rigid non-trivial flat irreducible connection  $R_j$  is given by the sum running over 3-valent graphs of expressions obtained by the standard Feynman rules. All summands are convergent integrals, and the sum does not depend on a choice of propagator.

Next I am going to explain how to construct an analog of the perverse sheaf  $\mathcal{F}$  on  $\mathbb{C}$  such that  $\mathbf{R}\Gamma(\mathbb{C}, \mathcal{F}) = 0$ . For that we will need a slightly different finite-dimensional model, since CS is multivalued.

## Finite-dimensional model

Let  $(X, vol, f)$  be a triple consisting of an  $n$ -dimensional complex manifold endowed with a holomorphic volume form  $vol$  and a holomorphic Morse function  $f : X \rightarrow \mathbb{C}^*$ . We assume that critical values of  $f$  is a finite set  $Critval(f)$ , and that  $f$  defines a locally trivial fiber bundle over the complement of the set of critical values.

Let  $exp(s/2\pi i) : \mathbb{C} \rightarrow \mathbb{C}^*$  be the universal abelian covering and  $(X_1, vol_1, f_1)$  be the pullback of the above data to the universal  $\mathbb{Z}$ -covering  $X_1 \rightarrow X$ . Then the set  $Critval(f_1)$  of critical values of  $f_1$  consists of finitely many arithmetic series, and  $f_1$  gives rise to a locally trivial fiber bundle outside of this set.

For any  $s_1 \in \mathbb{C} - Critval(f_1)$  we have an isomorphism

$$H_n(X_1, f_1^{-1}(s_1), \mathbb{Z}) \simeq \bigoplus_{z_i \in Critval(f_1)} H_n(f_1^{-1}(D_\varepsilon(z_i)), f_1^{-1}(z_i + \varepsilon e^{\sqrt{-1}Arg(\theta(\gamma(s_1, z_i)))}), \mathbb{Z}),$$

where  $D_\varepsilon(p)$  denote a small disc of radius  $\varepsilon$  with the center at  $p$ .

This isomorphism depends on a choice of infinite collection of paths  $\gamma(s_1, z_i)$  (Gabrielov paths) from  $s_1$  to the critical values  $z_i$  such that the paths are disjoint outside of  $s_1$ . Generically  $s_1$  does not belong to the countable set of straight lines through different pairs of critical values of  $f_1$ . Then there is a canonical choice of Gabrielov paths consisting of straight intervals. In this case  $\theta(\gamma(s_1, z_i)) = \text{Arg}(s_1 - z_i)$ . Let us assume for simplicity that we are in the generic case. The relative homology groups  $H_n(X_1, f_1^{-1}(s_1), \mathbb{Z})$  form a local system of infinite rank over  $\mathbb{C} - \text{Critval}(f_1)$ . In the case of Morse critical points the fiber can be identified with  $\mathbb{Z}[T^{\pm 1}] \otimes \mathbb{Z}^{\text{Critval}(f)}$ .

We would like to do the same thing in the case of the complexified Chern-Simons theory. CS functional is an analog of the function  $f_1$ , but now  $n = \infty$ . We do not want to develop a semi-infinite differential geometry in order to make the story completely similar to the finite-dimensional one. This is possible to do in case of Morse-Bott critical points, but not in general. We propose to use the cohomology with coefficients in the sheaf of vanishing cycles instead.

Then we replace each summand  $H_n(f_1^{-1}(D_\varepsilon(z_j)), f_1^{-1}(z_j + \varepsilon e^{\sqrt{-1} \text{Arg}(s_1 - z_j)}), \mathbb{Z})$  by the dual to the abelian group  $H^0(\mathcal{Z}_j(\alpha_{CS}), \varphi_{CS.e^{-\sqrt{-1} \text{Arg}(s_1 - z_j)}}(\mathbb{Z}))$ .

Combining all critical values together we obtain a local system of infinite rank. Its fiber over  $s_1 \in \mathbb{C} - \text{Critval}(CS)$  can be thought of as the “semi-infinite homology group”  $H_\infty(\widehat{\mathcal{A}}_{\mathbb{C}}^{fr}, CS^{-1}(s_1), \mathbb{Z})$ . In other words the fiber over generic  $s_1$  is isomorphic to the dual to the product

$$\prod_{z_j \in \text{Critval}(CS)} H^0(\mathcal{Z}_j(\alpha_{CS}), \varphi_{CS \cdot e^{-\sqrt{-1} \text{Arg}(s_1 - z_j)}}(\mathbb{Z})).$$

We will sometimes use the notation  $H_\infty(\widehat{\mathcal{A}}_{\mathbb{C}}^{fr}, CS^{-1}(s_1), \mathbb{Z})$  for this dual cohomology group, but you should remember that we do not have an alternative definition of the semi-infinite homology.

We expect that this local system can be extended to critical values of  $CS$  giving rise to a cosheaf of *countable* rank on  $\mathbb{C}$ . Keeping the notation  $\mathcal{F}_{CS}$  for the dual sheaf one can show that  $\mathbf{R}\Gamma(\mathbb{C}, \mathcal{F}_{CS}) = 0$  in agreement with the finite-dimensional case (warning: not quite trivial fact because of the failure of the Mittag-Leffler property).

# CS Hodge structure

- a) By analogy with the finite-dimensional case one can speculate that the abelian group  $H_\infty(\widehat{\mathcal{A}}_{\mathbb{C}}^{fr}, CS^{-1}(s_1), \mathbb{Z})$  carries a weight filtration of infinite rank, while the vector space  $H_\infty(\widehat{\mathcal{A}}_{\mathbb{C}}^{fr}, CS^{-1}(s_1), \mathbb{Z}) \otimes \mathbb{C}$  carries a Hodge filtration of infinite rank. In this sense one can speak about the **Chern-Simons Hodge structure of infinite rank**. We expect that the weight filtration is non-trivial (evidence: non-symmetry in the interaction of rigid critical flat connections  $\rho \neq 1$  and  $\rho = 1$ ).
- b) The sheaf  $\mathcal{F}_{CS}$  can be thought of as a “perverse sheaf of infinite rank”. Perverse extension to singular points should be possible because the non-trivial blocks of the monodromy matrices have finite size.
- c) By analogy with the finite-dimensional case one can hope that this “perverse sheaf of infinite rank” gives a wall-crossing structure. This “CS wall-crossing structure” is expected to be analytic. According to the **general resurgence conjecture** from our paper with Kontsevich [arXiv:2005.10651](https://arxiv.org/abs/2005.10651) analyticity of this WCS should imply resurgence of the local perturbative expansions in the CS theory.

# Resurgence of Chern-Simons local perturbative expansions

For each rigid flat connection  $\rho \neq 1$  with a trivial stabilizer consider the Borel transform  $\mathcal{B}(I_\rho(\hbar))$  of the corresponding (modified) local asymptotic expansion  $I_\rho(\hbar) \in \mathbb{C}[[\hbar]]$  of the complexified CS partition function. Since  $I_\rho(\hbar)$  is obtained by means of Feynman rules it is well-defined as a series in  $\hbar$ . Then after analytic continuation  $\mathcal{B}(I_\rho(\hbar)) := \mathcal{B}(I_\rho(\hbar))(s)$  has poles at the points  $s = s_m^\rho$  which belong to the arithmetic series  $z_\rho + (2\pi i)^2 m, m \in \mathbb{Z}$ , where  $z_\rho$  is the critical value of CS at  $\rho$ . Hence the general resurgence conjecture means that:

**Local perturbative expansion  $I_\rho(\hbar) \in \mathbb{C}[[\hbar]]$  at the rigid flat connection  $\rho \neq 1$  as above is resurgent.**

# Interaction of critical points

Furthermore the analytic continuation of the Borel transform of the germ  $\mathcal{B}(I_\rho(\hbar))$ ,  $\rho \neq 1$  along paths joining pairs of points  $s_m^\rho$  and  $s_l^{\rho'}$ ,  $\rho' \neq 1$  recovers the Borel transform  $\mathcal{B}(I_{\rho'}(\hbar))$ . In fact analytic continuation of the germ  $\varphi_{\rho,m}$  of the Borel transform  $\mathcal{B}(I_\rho(\hbar))(s)$  at  $s = s_m^\rho$  to the point  $s = s_l^{\rho'}$  has the form  $f_{m,l,\rho,\rho'}(s) + n_{m,l} \frac{\log(s-s_l^{\rho'})}{2\pi i} \varphi_{\rho',l}$ , where  $f_{m,l,\rho,\rho'}(s)$  is holomorphic in a neighborhood of  $s_l^{\rho'}$ , and  $n_{m,l} \in \mathbb{Z}$  is the Stokes index (=number of gradient lines of  $\operatorname{Re}(CS \cdot e^{-i\operatorname{Arg}(s_l^\rho - s_m^\rho)})$  joining corresponding critical points).

# CS Hodge structure and Borel transform

Consider  $\mathbb{Z}$ -linear combinations of analytic continuations of all germs  $\varphi_{\rho,m}$  along all paths in the set of non-critical values  $Noncr(CS) := \mathbb{C} - \{s_m^\rho\}$ . This gives a local system  $\mathcal{L}$  over  $Noncr(CS)$  with the generic fiber  $\mathbb{Z}^{\#\{s_m^\rho\}}$  as well as a homomorphism of sheaves  $\mathcal{L} \rightarrow \mathcal{O}_{Noncr(CS)}$ . In a punctured small neighborhood of  $s_m^\rho$  one has a sublattice  $\mathcal{L}' \subset \mathcal{L}$  of corank 1 of the monodromy-invariant elements. The latter contains in turn a sublattice  $\mathbb{Z} \cdot \varphi_{\rho,m}$ . The monodromy  $T_{s_m^\rho}$  about  $s_m^\rho$  is a block-diagonal matrix in the natural basis of analytically continued germs, with 1's on the diagonal except of the only non-trivial unipotent  $2 \times 2$  block with 1 above the diagonal.

Factorizing by the action of the group  $(2\pi i)^2 \mathbb{Z}$  one obtains the corresponding local system  $\overline{\mathcal{L}}$  on  $\mathbb{C}^* - \{\text{finite set}\}$ .

# Integration over the cycle of unitary connections

One can speculate about about the relation of the “honest” quantum CS partition function (i.e. the Feynman integral over the cycle of **unitary** framed connections) and the above hypothetical Hodge structure of infinite rank. We expect that the following conjecture holds: The group  $H_\infty(\widehat{\mathcal{A}}_C^{fr}, \text{Im}(CS) \ll 0, \mathbb{Z})$  has finite rank. It is canonically isomorphic to the direct sum of analogous local semi-infinite cohomology groups over the set of critical values of the CS functional. The “fundamental class”  $[\mathcal{A}_C^{fr}]$  defines an element in this vector space. In particular this means that the integral over the cycle of unitary connections (i.e. the quantum CS partition function) can be expressed as the sum of integrals over more accessible cycles e.g. thimbles. This is a generalization of the approach of Witten to analytically continued CS theory. We have more precise conjectures about this integral, but I do not have time for that.

## More explicit conjecture about the integral over the cycle of unitary connections

Let us fix the level  $k \in \mathbb{Z}_{\geq 1}$ . Then there exist cycles  $\gamma_{\rho_j}$  and  $n_{\rho_j} \in \mathbb{Z}$  such that

$$\int_{\mathcal{A}_c^{fr}} e^{\frac{kCS}{2\pi i}} \mathcal{D}A = \sum_{\rho_j, s.t. |\exp(CS(\rho_j)/2\pi i)| \leq 1} n_{\rho_j} \int_{\gamma_{\rho_j}} e^{\frac{kCS}{2\pi i}} \mathcal{D}A,$$

where  $n_{\rho_j} \in \mathbb{Z}$  is the virtual number solutions of the (generalized) Kapustin-Witten equation on  $M^3 \times [0, \infty)$  with the unitary boundary conditions at  $M^3 \times \{0\}$  and flat boundary conditions  $\rho_j, |\exp(CS(\rho_j)/2\pi i)| \leq 1$  at  $M^3 \times \{\infty\}$ . Here  $\gamma_{\rho_j}$  denote a cycle (i.e. a representative of an element of  $H_\infty(\widehat{\mathcal{A}}_C^{fr}, \text{Im}(CS) \ll 0, \mathbb{Z})$ ) emerging from the critical point  $\rho_j$  and satisfying the condition  $\text{Re}(kCS/2\pi i) < 0$  along the cycle.

By analogy with finite-dimensional case we may assume that the integrals over the thimbles in the above Conjecture give sections of the holomorphic bundle of finite rank over a small punctured disc in  $\mathbb{C}_{\hbar}$ . The Conjecture guarantees that the LHS is also a holomorphic section of this bundle. One can speculate that the values of this section at the points  $\hbar = 2\pi i/k, k = 1, 2, \dots$  coincide with the corresponding Reshetikhin-Turaev invariants  $RT_k$ .

# Analyticity conjecture

Consider the generating function

$$N(w) = \sum_{1 \leq k \leq \infty} \left( \int_{\mathcal{A}_c^{fr}} e^{kCS(A)/2\pi i} \mathcal{D}A \right) w^k.$$

**If the above-defined WCS for the CS theory is analytic then the generating series  $N(w)$  converges in the disc  $|w| < 1$  and analytically continues to  $\mathbb{C}$  with singularities at  $\{0\} \cup \text{Critval}(CS)$ .**

There is a finite-dimensional toy-model example illustrating the conjecture. Namely, let  $f = z - \log(z)$  and  $I_k = \int_{|z|=1} e^{kf(z)} \frac{dz}{z}$ . Then  $I_k = \frac{1}{2\pi i} \int_{|z|=1} z^{-k} e^{kz} \frac{dz}{z} = \frac{k^k}{k!}$ . Consider the generating function  $N(w) = \sum_{k \geq 1} w^k k^k / k!$ . This function has ramifications at the critical values of  $f$  i.e. at  $0, e^{-1}, \infty$ . Setting  $0^0 = 1$  we can rewrite  $N(w)$  such as follows

$$N(w) = \sum_{k \geq 0} \frac{1}{2\pi i} w^k \int_{|z|=1} (e^z/z)^k \frac{dz}{z} = \frac{1}{2\pi i} \int_{|z|=1} \frac{1}{w^{-1} - \frac{e^z}{z}} \frac{dz}{z}.$$

The poles  $z_n(w)$ ,  $n \geq 1$  of the denominator  $w^{-1} - \frac{e^z}{z}$  form a countable subset of  $\mathbb{C}$ , and the group  $H_1(\mathbb{C}^* - \{z_n(w)\}_{n \geq 1}, \mathbb{Z})$  is generated by the cycle  $|z| = 1$  and small circles about the poles. One can show that  $\int_{|z - z_n(w)| \ll 1} \frac{1}{w^{-1} - \frac{e^z}{z}} \frac{dz}{z} = 1 + \frac{1}{z_n(w)}$ . The generic fiber of the homology bundle carries two permutations: one is a permutation of two elements, while the other one is an infinite cyclic shift. Making the analogy with the CS functional we see that the cycle about 0 corresponds to the trivial local system  $\rho = 1$ , while other cycles give residues and correspond to rigid local systems  $\rho \neq 1$ .

# Explicit description of the WCS for the Chern-Simons theory

In the case of the CS-functional the group of periods of the holomorphic 1-form  $\alpha_{CS} = dCS$  is  $(2\pi i)^2 \mathbb{Z} \simeq \mathbb{Z}$ . Consider the holomorphic function  $f_{CS} = \exp(CS/2\pi i)$  which has only finitely many critical values. Then the WCS is defined in terms of the following data:

- 1)  $\Gamma = H_1(\mathbb{C}^*, \text{Critval}(f_{CS}), \mathbb{Z})$ , and  $Z : \Gamma \rightarrow \mathbb{C}$  given by  $Z(\gamma) = \int_{\gamma} \frac{dw}{w}$ .
- 2) Central charge  $Z : \Gamma \rightarrow \mathbb{C}, \gamma \mapsto 2\pi i \int_{\gamma} \frac{dw}{w}$ .

3) Local system of  $\Gamma$ -graded Lie algebras  $\underline{\mathfrak{g}}$  on  $\mathbb{C}_{\hbar}^*$  with the fiber given by

$$\mathfrak{g}_{\hbar} := \bigoplus_{\gamma \in \Gamma} \mathfrak{g}_{\hbar, \gamma} =$$

$$\bigoplus_{j_1, j_2} \text{Hom}(H^0(\mathcal{Z}_{j_1}(\alpha_{CS}), \varphi_{\frac{CS}{\hbar}}(\mathbb{Z})), H^0(\mathcal{Z}_{j_2}(\alpha_{CS}), \varphi_{\frac{CS}{\hbar}}(\mathbb{Z})) \otimes \mathbb{C}$$

where the summation is taken over the set  $\{w_1, w_2 \in \text{Critval}(f_{CS}), \gamma \in \Gamma \text{ s.t. } \partial\gamma = [w_1] - [w_2], j_1, j_2 \in J \text{ s.t. } f_{CS|_{\mathcal{Z}_{j_m}}}(\alpha_{CS}) = \hbar w_m, m = 1, 2\}$ .

4) For any  $\hbar \in \mathbb{C}^*$  we define the pronilpotent completion  $\widehat{\mathfrak{g}}_{\hbar} = \prod_{Z(\gamma) \in \hbar \cdot \mathbb{R}_{>0}} \mathfrak{g}_{\gamma, \hbar}$ . Let  $G_{\hbar} = \exp(\widehat{\mathfrak{g}}_{\hbar})$  be the corresponding pronilpotent group. The pronilpotent Lie algebra  $\widehat{\mathfrak{g}}_{\hbar}$  is well-defined because the corresponding set of  $\gamma$  with  $\mathfrak{g}_{\hbar, \gamma} \neq 0$  belongs to a strict convex cone. The Stokes automorphisms  $A_{\hbar} := A_{I_{\hbar}} \in G_{\hbar}$  are not equal to 1 for at most countable set of rays  $I_{\hbar} := \{Arg(\hbar) = const\}$ . In general the Stokes automorphisms are not well-understood even at the physics level of rigor. One expects that they can be derived from the study of a generalization of Kapustin-Witten equations to the case of non-Morse critical points of the CS functional. For isolated Morse critical points the Stokes automorphisms are derived from a collection of integers (Stokes indices). They can be interpreted as the number of gradient lines of the function  $Re(CS/\hbar)$  between the corresponding critical points.

THANK YOU!
